12 **ABSTRACT**

13 During past geological times, the Earth experienced several intervals of global warmth, but their driving
14 factors remain equivocal. A careful appraisal of the main processes involved in these controlling past warm events
15 is essential to evaluate how they can inform future climates and ultimately provide decision makers with a clear
16 understanding of the processes at play in a warmer world. In this context, intervals of greenhouse climates, such
17 as the thermal maximum of the Cenomanian-Turonian (~94 Ma) during the Cretaceous period, are of particular
18 interest. Here we use the IPSL-CM5A2 Earth System Model to unravel the forcing parameters of the Cenomanian-
19 Turonian greenhouse climate. We perform six simulations with an incremental change in five major boundary
20 conditions in order to isolate their respective role on climate change between the Cenomanian-Turonian and the
21 preindustrial. Starting with a preindustrial simulation, we implement the following changes in boundary
22 conditions: (1) the absence of polar ice sheets, (2) the increase in atmospheric $p\text{CO}_2$ to 1120 ppm, (3) the change
23 of vegetation and soil parameters, (4) the 1% decrease in the Cenomanian-Turonian value of the solar constant
24 and (5) the Cenomanian-Turonian paleogeography. Between the preindustrial simulation and the Cretaceous
25 simulation, the model simulates a global warming of more than 11°C. Most of this warming is driven by the
26 increase in atmospheric $p\text{CO}_2$ to 1120 ppm. Paleogeographic changes represent the second major contributor to
27 global warming, while whereas the reduction in the solar constant counteracts most of geographically-driven
28 global warming. We further demonstrate that the implementation of Cenomanian-Turonian boundary conditions
29 flattens meridional temperature gradients compared to in the preindustrial simulation. Interestingly, we show
30 that paleogeography is the major driver of the flattening in the low- to mid-latitudes, whereas $p\text{CO}_2$ rise and polar
31 ice sheet retreat dominate the high-latitude response.

32 1. INTRODUCTION

33 The Cretaceous period is of particular interest to understand drivers of past greenhouse climates
34 because intervals of prolonged global warmth (O'Brien et al. 2017, Huber et al. 2018) and elevated atmospheric
35 CO₂ levels (Wang et al., 2014), possibly similar to future levels, have been documented in the proxy record. The
36 thermal maximum of the Cenomanian-Turonian (CT) interval (94 Ma) represents the acme of Cretaceous
37 warmth, during which one of the most important carbon cycle perturbation of the Phanerozoic
38 occurred: the oceanic anoxic event 2 (OAE2). Valuable understanding of what controls large-scale climate
39 processes can hence be drawn from investigations of the mechanisms responsible for the CT thermal maximum
40 and carbon cycle perturbation.

41 Proxy-based reconstructions and model simulations of sea-surface temperatures (SST) for the CT reveal
42 that during OAE2 the equatorial Atlantic was 4-6° warmer than today (Norris et al., 2002; Bice et al., 2006; Pucéat
43 et al., 2007; Tabor et al., 2016), and possibly even warmer that that (6-9° - Forster et al., 2007). This
44 short and abrupt episode of major climatic, oceanographic, and global carbon cycle perturbations occurred at the
45 CT Boundary and was superimposed on a long period of global warmth (Jenkyns, 2010). The high
46 latitudes were also much warmer than today (Herman and Spicer, 2010; Spicer and Herman, 2010), as was the
47 abyssal ocean which experienced bottom temperatures reaching up to 20°C during the CT (Huber
48 et al., 2002; Littler et al., 2011; Friedrich et al., 2012). Paleobotanical studies suggest that the atmosphere was
49 also much warmer (Herman and Spicer, 1996), with high-latitude temperatures
50 up to 17°C higher than today (Herman and Spicer, 2010) and possibly reaching annual means of 10-12°C in
51 Antarctica (Huber et al., 1999).

52 The steepness of the equator-to-pole gradient is still a matter of debate, in particular because of
53 inconsistencies between data and models as the latter usually predict steeper gradients than those
54 reconstructed from proxy data (Barron, 1993; Huber et al., 1995; Heinemann et al., 2009; Tabor et al., 2016).
55 Models and data generally agree, however, that Cretaceous sea-surface temperature (SST) gradients were
56 reduced compared to today (Sellwood et al., 1994; Huber et al., 1995; Jenkyns et al., 2004; O'Brien et al.,
57 2017; Robinson et al., 2019).

58 The main factor generally considered responsible for the Cretaceous global warm climate is the higher
59 atmospheric CO₂ concentration (Barron et al., 1995; Crowley and Berner, 2001; Royer et al., 2007; Wang et al.,
60 2014; Foster et al., 2017). This has been determined by proxy-data reconstructions of the Cretaceous

Commented [MG1]: I think we need a reference here

61 $p\text{CO}_2$ using various techniques, including analysis of paleosols $\delta^{13}\text{C}$ (Sandler and Harlavan, 2006; Leier et al., 2009;
62 Hong and Lee, 2012), liverworts $\delta^{13}\text{C}$ (Fletcher et al., 2006) or phytane $\delta^{13}\text{C}$ (Damsté et al., 2008; Van Bentum et
63 al., 2012) and leaf stomata analysis (Barclay et al., 2010; Mays et al., 2015; Retallack and Conde, 2020). Modelling
64 studies have also focused on estimating Cretaceous atmospheric CO_2 levels (Barron et al., 1995; Poulsen et al.,
65 2001, 2007; Berner, 2006; Bice et al., 2006; Monteiro et al., 2012) in an attempt to refine the large spread in
66 values inferred from proxy data (from less than 900 ppm to over 5000 ppm). The typical atmospheric $p\text{CO}_2$
67 concentration resulting from these studies for the CT averages around a long-term value of 1120 ppm (Barron et
68 al., 1995; Bice and Norris, 2003; Royer, 2013; Wang et al., 2014), e.g., four times the
69 preindustrial value (280 ppm = 1 P.A.L : “Preindustrial Atmospheric Level”). Atmospheric $p\text{CO}_2$ levels are,
70 however, known to vary on shorter timescales during the period, in particular during OAE2. It has indeed been
71 suggested that this event may have been caused by a large increase in atmospheric $p\text{CO}_2$ concentration, possibly
72 reaching 2000 ppm or even higher, because of volcanic activity in large igneous provinces
73 (Kerr and Kerr, 1998; Turgeon and Creaser, 2008; Jenkyns, 2010). The proxy records suggest that
74 the $p\text{CO}_2$ levels may have dropped down to 900 ppm after carbon sequestration into organic-rich marine
75 sediments (Van Bentum et al., 2012).

76 Paleogeography is also considered as a major driver of climate change through geological times (Crowley
77 et al., 1986; Gyllenhaal et al., 1991; Goddérís et al., 2014; Lunt et al., 2016). Several processes linked to
78 paleogeographic changes have been shown to impact Cretaceous climates. These processes include albedo and
79 evapotranspiration feedbacks from paleovegetation (Otto-bliesner and Upchurch, 1997), seasonality due to
80 continental break-up or presence of epicontinental seas (Fluteau et al., 2007), atmospheric feedbacks due to
81 water cycle modification (Donnadieu et al., 2006), Walker and Hadley cells changes after Gondwana break-up
82 (Ohba and Ueda, 2011), or oceanic circulation changes due to gateways opening (Poulsen et al., 2001, 2003).
83 Other potential controlling factors include the time-varying solar constant (Gough, 1981), whose impact on
84 Cretaceous climate evolution was quantified by Lunt et al. (2016), and changes in the distribution of vegetation,
85 which has been suggested to drive warming, especially in the high-latitudes with a temperature increase of up to
86 $4^{\circ}\text{--}10^{\circ}\text{C}$ in polar regions (Otto-bliesner and Upchurch, 1997; Brady et al., 1998; Upchurch, 1998; Deconto et al.,
87 2000; Hunter et al., 2013).

88 Despite all these studies, there is no established consensus on the relative importance of each of
89 the controlling factors on the CT climate. In particular, the primary driver of the Cretaceous climate has been

suggested to be either $p\text{CO}_2$ or paleogeography. Early studies suggested a negligible role of paleogeography on global climate compared to the high CO_2 concentration (Barron et al., 1995) whereas others suggested that CO_2 was not the primary control (Veizer et al., 2000) or that the impact of paleogeography on climate was as important as a doubling of $p\text{CO}_2$ (Crowley et al., 1986). More recent modeling studies have also suggested that paleogeographic changes could affect global climate (Poulsen et al., 2003; Donnadieu et al., 2006; Fluteau et al., 2007) but their impact remain debated (Ladant and Donnadieu, 2016; Lunt et al., 2016; Tabor et al., 2016). For example, the simulations of Lunt et al. (2016) support a key role of paleogeography at the regional rather than global scale, and show that the global paleogeographic signal is cancelled by an opposite trend due to changes in the solar constant. Tabor et al. (2016) also suggest important regional climatic impacts of paleogeography, but argue that CO_2 is the main driver of the Late Cretaceous climate evolution. In contrast, Ladant and Donnadieu (2016) find a large impact of paleogeography on the global mean Late Cretaceous temperatures; their signal is roughly comparable to a doubling of atmospheric $p\text{CO}_2$. Finally, the role of paleovegetation is also uncertain as some studies show a major role at high-latitude (Upchurch, 1998; Hunter et al., 2013), whereas a more recent study instead suggests limited impact at high latitudes ($<2^\circ\text{C}$) with a cooling effect at low latitudes under high $p\text{CO}_2$ values (Zhou et al., 2012).

In this study, we investigate the forcing parameters of CT greenhouse climate by using a set of simulations run with the IPSL-CM5A2 Earth System Model. We perform six simulations, using both preindustrial and CT boundary conditions, where we incrementally modify the preindustrial boundary conditions to that of the CT. The changes are as follows: (1) the removal of polar ice sheets, (2) an increase in $p\text{CO}_2$ to 1120 ppm, (3) the change of vegetation and soil parameters to those found during the CT, (4) a 1% reduction in the value of the solar constant, and (5) the implementation of Cenomanian-Turonian paleogeography. We particularly focus on processes driving warming or cooling of atmospheric surface temperatures after each change in boundary condition change to study the relative importance of each parameter in the CT to preindustrial climate change. We also investigate how the SST gradient responds to boundary condition changes to understand the evolution of its steepness between the CT and the preindustrial.

2. MODEL DESCRIPTION & EXPERIMENTAL DESIGN

2.1 IPSL-CM5A2 MODEL

118 IPSL-CM5A2 is an updated version of the IPSL-CM5A-LR earth system model developed at IPSL (Institut
119 Pierre-Simon Laplace) within the CMIP5 framework (Dufresne et al., 2013). It is a fully-coupled Earth
120 System Model, which simulates the interactions between atmosphere, ocean, sea ice, and land surface. The
121 model includes the marine carbon and other key biogeochemical cycles (C, P, N, O, Fe and Si - See Aumont et al.,
122 2015). Its former version, IPSL-CM5A-LR, has a rich history of applications, including present-day and future
123 climates (Aumont and Bopp, 2006; Swingedouw et al., 2017) as well as preindustrial (Gastineau et al., 2013) and
124 paleoclimate studies (Kageyama et al., 2013; Contoux et al., 2015; Bopp et al., 2017; Tan et al., 2017; Sarr et al.,
125 2019). It was also part of IPCC AR5 and CMIP5 projects (Dufresne et al., 2013),
126 . IPSL-CM5A-LR has also been used to explore links between marine productivity and climate (Bopp et al., 2013;
127 . IPSL-CM5A-LR has also been used to explore links between marine productivity
128 and climate (Bopp et al., 2013; Le Mézo et al., 2017; Ladant et al., 2018), vegetation and climate (Contoux et al.,
129 2013; Woillez et al., 2014), and topography and climate (Maffre et al., 2018), but also the role of nutrients in the
130 global carbon cycle (Tagliabue et al., 2010) or the variability of oceanic circulation and upwelling (Ortega et al.,
131 2015; Swingedouw et al., 2015). Building on recent technical developments, IPSL-CM5A2 provides enhanced
132 computing performances compared to IPSL-CM5A-LR, allowing thousand year-long integrations required for
133 deep-time paleoclimate applications or long-term future projections (Sepulchre et al., 2019). It thus
134 reasonably simulates modern-day and historical climates (despite some biases in the tropics), whose complete
135 description and evaluation can be found in Sepulchre et al., 2019.

136 IPSL-CM5A2 is composed of the LMDZ atmospheric model (Hourdin et al., 2013), the
137 ORCHIDEE land surface and vegetation model (including the continental hydrological cycle, vegetation, and
138 carbon cycle; Krinner et al., 2005) and the NEMO ocean model (Madec, 2012), including the LIM2 sea-ice
139 model (Fichefet and Maqueda, 1997) and the PISCES marine biogeochemistry model (Aumont et al., 2015). The
140 OASIS coupler (Valcke et al., 2006) ensures a good synchronization of the different components and the XIOS
141 input/output parallel library is used to read and write data. The LMDZ atmospheric component has a horizontal
142 resolution of 96x95, (equivalent to 3.75° in longitude and 1.875° in latitude) and 39 uneven vertical levels.
143 ORCHIDEE shares the same horizontal resolution whereas NEMO – the ocean component – has 31 uneven
144 vertical levels (from 10 meters at the surface to 500 meters at the bottom), and a horizontal resolution of
145 approximately 2°, enhanced to up to 0.5° in latitude in the tropics. NEMO uses the ORCA2.3 tripolar grid to
146 overcome the North Pole singularity (Madec and Imbard, 1996).

2.2 EXPERIMENTAL DESIGN

150
151
152
153
154
155
156
157

Six simulations were performed for this study: one preindustrial control simulation, named piControl, and five simulations for which the boundary conditions were changed one at a time to progressively reconstruct the CT climate (see Table 1 for details). The scenarios are called 1X-NOICE (with no polar ice caps), 4X-NOICE (no polar ice caps + pCO₂ at 1120 ppm), 4X-NOICE-PFT-SOIL (previous changes + implementation of idealized Plant Functional Types (PFTs) and mean parameters for soil), 4X-NOICE-PFT-SOIL-SOLAR (previous changes + reduction of the solar constant) and 4X-CRETACEOUS (previous changes + CT paleogeography). The piControl simulation has been run for 1800 years and the five others for 2000 years in order to reach near-surface equilibrium (see Fig.1).

158

2.2.1 BOUNDARY CONDITIONS

159
160
161
162
163
164
165

As most evidence suggests the absence of permanent polar ice sheets during the CT (MacLeod et al., 2013; Ladant and Donnadieu, 2016; Huber et al., 2018), we remove polar ice sheets in our simulations (except in piControl) and we adjust topography to account for isostatic rebound resulting from the loss of the land ice covering Greenland and Antarctica (See Supplementary Figure 1). Ice sheets are replaced with brown bare soil and the river routing stays unchanged.

166
167
168

In the 4X simulations (i.e., all except piControl and 1X-NOICE), pCO₂ is fixed to 1120 ppm (4x P.A.L), a value reasonably close to the mean suggested by a recent compilation of CT pCO₂ reconstructions (Wang et al., 2014).

169
170
171
172
173
174
175

In the 4X-NOICE-PFT-SOIL simulation, the distribution of the 13 standard PFTs defined in ORCHIDEE is uniformly reassigned along latitudinal bands, based on a rough comparison with the preindustrial distribution of vegetation, in order to obtain a theoretical latitudinal distribution usable for any geological period. The list of PFTs and associated latitudinal distribution and fractions are described in Supplementary Table 1. Mean soil parameters, i.e., mean soil color and texture (rugosity), are calculated from preindustrial maps (Zobler, 1999; Wilson and Henderson-sellers, 2003) and uniformly prescribed on all continents. The impact of these idealized PFTs and mean parameters is discussed in the results.

Commented [MG2]: Marie, I think this can be deleted You talk about the scenarios in detail below, and you will save some space and avoid repetition this way.

Commented [MG3]: If you do delete the above part, add here that « This scenario is referred to as 1X-NOICE in the following «

176 The 4X-NOICE-PFT-SOIL-SOLAR simulation is initialized from the same conditions as 4X-NOICE-PFT-SOIL
177 except that the solar constant is reduced to its CT value (Gough, 1981). We use here the value of 1353.36 W/m²
178 (98.9% of the modern solar luminosity, calculated for an age of 90 My).

179 The 4X-CRETACEOUS simulation, finally, incorporates the previous modifications plus the implementation
180 of the CT paleogeography. The land-sea configuration used here is that proposed by Sewall (2007), in which we
181 have implemented the bathymetry from Müller (2008) (see Fig. 2). These bathymetric changes are done
182 to represent deep oceanic topographic features, such as ridges, that are absent from the Sewall paleogeographic
183 configuration. In this simulation, the mean soil color and rugosity as well as the theoretical latitudinal PFTs
184 distribution are adapted to the new land-sea mask and the river routing is recalculated from the new topography.
185 We also modify the tidally driven mixing associated with dissipation o internal wave energy
186 for the M2 and K1 tidal components from present day values (de Lavergne et al., 2019). The parameterization
187 used for simulations with the modern geography follows Simmons et al. (2004), with refinements in the modern
188 Indonesian Through Flow (ITF) region according to Koch-Larrouy et al. (2007). To create a Cenomanian-Turonian
189 tidal dissipation forcing, we calculate an M2 tidal dissipation field using the Oregon State University Tidal
190 Inversion System (OTIS, Egbert et al., 2004; Green and Huber, 2013). The M2 field is computed using our
191 Cenomanian-Turonian bathymetry and an ocean stratification taken from an unpublished equilibrated
192 Cenomanian-Turonian simulation realized with the IPSLCM5A2 with no M2 field. In the absence of any estimation
193 for the CT, we prescribe the K1 tidal dissipation field to 0. In addition, the parameterization of Koch-Larrouy et al.
194 (2007) is not used here because the ITF does not exist in the Cretaceous.

195 2.2.2 INITIAL CONDITIONS

196 The piControl and 1X-NOICE simulations are initialized with conditions from the Atmospheric Model
197 Intercomparison Project (AMIP) which were constrained by realistic sea surface temperature (SST)
199 and sea ice from 1979 to near present (Gates et al., 1999).

201

3. RESULTS

The simulated changes between the preindustrial (piControl) and the CT (4X-CRETACEOUS) simulations can be decomposed into five components based on our boundary condition changes: (1) Polar ice sheet removal (Δice), (2) $p\text{CO}_2$ (ΔCO_2), (3) PFT and Soil parameters ($\Delta\text{PFT-SOIL}$), (4) Solar constant (Δsolar) and (5) Paleogeography (Δpaleo). Each contribution to the total climate change can be calculated by a linear factorization (Broccoli and Manabe, 1987; Von Deimling et al., 2006), which simply corresponds to the anomaly between two consecutive simulations. The choice of applying a linear factorization approach was made for due to problems of computing time and cost. Changing the sequence of changes or applying a symmetrical factorization as in Lunt et al (2012b) would require too many supplementary simulations; Such at these methods is dependent depend on the sequence of changes, and the intensity of simulated warming/cooling for each component could differ if boundary conditions were changed in a different order (Lunt et al., 2012b), and the costs would be too high for this study. The results presented in the following are averages calculated over the last 100 simulated years.

3.1 GLOBAL CHANGES

The progressive change of parameters made to reconstruct the CT climate induces a general global warming (Table 2, Fig. 3). The annual global atmospheric ice temperature at 2 meters above the surface (T2M) rises from 13.25°C to 24.35 °C between the preindustrial and CT simulations. Every-All changes in boundary conditions generates a warming signal at the on a global scale, at-with the exception of the decrease in solar constant that-which generates a cooling. Most of the warming is due to the fourfold increase in atmospheric $p\text{CO}_2$, which alone increases the global mean temperature by 9°C. Paleogeographic changes also represent a major contributor to the warming, leading to an increase in T2M of 2.6°C. In contrast, the decrease in solar constant leads to a cooling of 1.8°C at the global scale. Finally, changes in the soil parameters and PFTs, as well as the retreat of polar caps, have smaller impacts, leading to increases in global mean T2M of 0.8°C and 0.5°C respectively.

Temperature changes exhibit different geographic patterns (Fig. 4) depending on the altered-which parameter is changed. These patterns range from global and uniform cooling (Δsolar – Fig 4e) to a global, polar-amplified, warming ($\Delta p\text{CO}_2$ – Fig 4c), as well as heterogeneous regional responses (Δice or Δpaleo – Fig 4b and 4f). In the next section, we describe the main patterns of change and the main feedbacks arising.

Commented [MG4]: How about this is changed to

The choice of applying a linear factorization approach was made due to computing time and cost. We appreciate that another sequence of changes could lead to a different final state, but as we show in section 4, our results are within the ranges provided by existing proxies for the CT. The computational costs would be too high for this study to explore this further here; it is an interesting problem that we leave for a future investigation.

Table 2: Simulations results (Global annual mean over last 100 years of simulation).

240
241

242 3.2 The major contributor to global warming - ΔCO_2

243 As mentioned above, the fourfold increase in $p\text{CO}_2$ leads to a global warming of 9°C (Table 3,
244 Fig. 3) between the 1X-NOICE and the 4X-NOICE simulations. The whole Earth warms, with an
245 amplification located over the Arctic and Austral oceans and a warming generally larger over
246 continents than over oceans (Fig 4c). The warming is due to a general decrease of planetary albedo
247 and of the atmosphere's emissivity (see Supplementary Figure 2). The decrease in the atmosphere's
248 emissivity is directly driven by the increase in CO_2 , and thus greenhouse trapping in the atmosphere. It
249 is also amplified by an increase in high-altitude cloudiness (defined as cloudiness at atmospheric
250 pressure < 440 hPa) over the Antarctic continent (Fig 5a, b). The decrease in planetary albedo is due to
251 two major processes. First, a decrease of sea ice and snow cover (especially over Northern
252 Hemisphere continents and along the coasts of Antarctica), leading to surface albedo decrease,
253 explains the warming amplification over polar oceans and continents. Second, a decrease in low-
254 altitude cloudiness (defined as cloudiness at atmospheric pressure > 680 hPa) at all latitudes except
255 over the Arctic (Fig 5a, b) leads to an increase in absorbed solar radiation.

256 The contrast in the atmospheric response over continents and oceans is due to the impact of
257 the evapo-transpiration feedback. Oceanic warming drives an increase in evaporation, which acts as a
258 negative feedback and moderates the warming by consuming more latent heat at the ocean surface.
259 In contrast, high temperatures resulting from continental warming tend to inhibit vegetation
260 development, which acts as positive feedback and enhances the warming due to reduced
261 transpiration and reduced latent heat consumption.

262

263 3.3 Boundary conditions with the smallest global impacts – Δice , $\Delta\text{PFT-SOIL}$, Δsolar

264 The removal of polar ice sheets in the 1X-NOICE simulation leads to a weak global warming of
265 0.5°C but a strong regional warming observed over areas previously covered by the Antarctic and
266 Greenland ice sheets (Fig 4a, b). This signal is due to the combination of a decrease in elevation (i.e.,

lapse rate feedback – Supplementary Figure S3) and in surface albedo, which is directly linked to the shift from a reflective ice surface to a darker bare soil surface. Unexpected cooling is also simulated in specific areas, such as the margins of the Arctic Ocean and the southwestern Pacific. These contrasted climatic responses to the impact of ice sheets on sea surface temperatures are consistent with previous modeling studies (Goldner et al., 2014; Knorr and Lohmann, 2014; Kennedy et al., 2015). Their origin is still unclear but changes in winds in the Southern Ocean, due to topographic changes after polar ice sheet removal, may locally impact oceanic currents, deep-water formation, and thus oceanic heat transport and temperature distribution. In the Northern Hemisphere, the observed cooling over Eurasia could be linked to stationary wave feedbacks following changes in topography after Greenland ice sheet removal (Supplementary Figure S4; see also Maffre et al., 2018).

The change in soil parameters and the implementation of theoretical zonal PFTs in the 4X-NOICE-PFT-SOIL simulation drive a warming of 0.8 °C. This warming is essentially located above arid areas, such as the Sahara, Australia, or Middle East, and polar latitudes (Antarctica/Greenland) (Fig 4d), and is mostly caused by the implementation of a mean uniform soil color, which drives a surface albedo decrease over deserts that normally have a lighter color. The warming at high-latitudes is linked to vegetation change: bare soil that characterizes continental regions previously covered with ice is replaced by boreal vegetation with a lower surface albedo. The presence of vegetation at such high-latitudes is consistent with high-latitude paleobotanical data and temperature records during the Cretaceous (Otto-bliesner and Upchurch, 1997; Herman and Spicer, 2010; Spicer and Herman, 2010).

Finally, the change in solar constant from 1365 W/m² to 1353 W/m² (Gough 1981) directly drives a cooling of 1.8 °C evenly distributed over the [planet](#) (Fig 4e).

3.4 The most complex response - Δpaleogeography

The paleogeographic change drives a global warming of 2.6 °C. This is seen year-round in the Southern Hemisphere, while the Northern Hemisphere experiences [a](#) warming during winter and cooling during summer [compared to pre-industrial conditions](#) (Fig 6). These temperature changes are linked to a general decrease in planetary albedo and/or emissivity, although the Northern Hemisphere sometimes exhibits increased albedo, due to the increase in low-altitude cloudiness. This increase in albedo is compensated by a strong atmosphere emissivity decrease during winter but not during summer, which leads to the seasonal pattern of cooling and warming (Supplementary Figure S5).

The albedo and emissivity changes are linked to atmospheric and oceanic circulation modifications driven by [four](#) major features of the CT paleogeography (Fig 2):

- (1) Equatorial oceanic gateway opening (Central American Seaway/Neotethys)
- (2) Polar gateway closure (Drake/Tasman)

(3) Increase in oceanic area in the North Hemisphere (Fig 2)

(4) Decrease in oceanic area in the South Hemisphere (Fig 2)

In the CT simulation, we observe an intensification of the meridional surface circulation and extension towards higher latitudes compared to the simulation with the modern geography (Fig8a-b), as well as an intensification of subtropical gyres, especially in the Pacific (Supplementary Figure S6), which are responsible for an increase in poleward oceanic heat transport (OHT – Fig 8c). Such modifications can be linked to the opening of equatorial gateways that creates a zonal connection between the Pacific, Atlantic and Neotethys oceans (Enderton and Marshall, 2008; Hotinski and Toggweiler, 2003) and that leads to the formation of a strong circumglobal equatorial current (Fig 7b). This connection permits the existence of stronger easterly winds that enhance equatorial upwelling and drive increased export of water and heat from low latitudes to polar regions. In the Southern Hemisphere, the Drake Passage is only open to shallow flow, and the Tasman gateway has not yet formed. The closure of these zonal connections leads to the disappearance of the modern Antarctic Circumpolar Current (ACC) during the Cretaceous (Fig 7c-d). Notwithstanding, the observed increase in southward OHT between 40° and 60°S (Fig 8c) is explained by the absence of significant zonal connections in the Southern Ocean, which allows for the buildup of polar gyres in the CT simulation (Supplementary Figure S6).

The increase in OHT is associated with a meridional expansion of high sea-surface temperatures leading to an intensification of evaporation between the tropics and a poleward shift of the ascending branches of the Hadley cells. The combination of these two processes results in a greater injection of moisture into the atmosphere between the tropics (Supplementary Figure S7). Consequently, the high-altitude cloudiness increases and spreads towards the tropics, leading to an enhanced greenhouse effect. This process is the main driver of the intertropical warming (Herweijer et al., 2005; Levine and Schneider, 2010; Rose and Ferreira, 2013).

The atmosphere's response to the paleogeographic changes in the mid- and high-latitudes is different in the Southern and Northern Hemispheres because the ocean to land ratio varies between the CT configuration and the modern. In the Southern Hemisphere, the reduced ocean surface area (Fig 2) limits evaporation and moisture injection into the atmosphere, which in turn leads to a decrease in relative humidity and low-altitude cloudiness (Supplementary Fig S8) and associated year-round warming due to reduced planetary albedo. In the Northern Hemisphere, oceanic surface area increases (Fig 2) and results in a strong increase in evaporation and moisture injection into the atmosphere. Low-altitude cloudiness and planetary albedo increase and lead to summer cooling, as discussed above (Fig 6). During winter an increase in high-altitude cloudiness leads to an enhanced greenhouse effect and counteracts the larger albedo. This high-altitude cloudiness increase is

Commented [MG5]: in the CT simulation ? please specify

consistent with the simulated increase in extratropical OHT (Fig. 8). Mid-latitude convection and moist air injection into the upper troposphere is consequently enhanced and efficiently transported poleward (Rose and Ferreira, 2013; Ladant and Donnadieu, 2016). In addition, increased continental fragmentation in the CT paleogeography relative to the preindustrial decreases the effect of continentality (Donnadieu et al. 2006) because thermal inertia is greater in the ocean than over continents.

3.5 Temperature Gradients

3.5.1 Ocean

The mean annual global SST increases as much as 9.8°C (from 17.9°C to 27.7 °C) across the simulations. The SST warming is slightly weaker than that of the mean annual global atmospheric temperature at 2m discussed above, and most likely occurs because of evaporation processes due to the weaker atmospheric warming simulated above oceans compared to that simulated above continents. Unsurprisingly, as for the atmospheric temperatures, $p\text{CO}_2$ is the major controlling parameter of the ocean warming (7°C), followed by paleogeography (4.5°C) and changes in the solar constant (2.3°C), although the latter induces a cooling rather than a warming. PFT and soil parameter changes and the removal of polar ice sheets have a minor impact at the global SST (0.6 °C and 0°C respectively). It is interesting to note the increased contribution of paleogeography to the simulated SST warming compared to its contribution to the simulated atmospheric warming, which is probably driven by the major changes simulated in surface ocean circulation (Fig. 7).

Mean annual SST in the preindustrial simulation reach ~ 26°C in the tropics (calculated as the zonal average between 30°S and 30°N) and ~ -1.5°C at the poles (beyond 70° N - Fig 9a). In this work, we define the meridional temperature gradients as the linear temperature change per 1° of latitude between 30° and 80°. The gradients in the piControl experiment then amount to 0.45°C/°latitude and 0.44°C/°latitude for the Northern and Southern Hemispheres, respectively. In the CT simulation, the mean annual SST reach ~ 33.3°C in the tropics, and ~5°C and 10°C in the Arctic and Southern Ocean respectively, and the simulated CT meridional gradients are 0.45°C/°latitude and 0.39°C/°latitude for the Northern and Southern Hemispheres, respectively.

The progressive flattening of the SST gradient can be visualized by superimposing the zonal mean temperatures of the different simulations and by adjusting them at the Equator (Fig 9b). Two major observations can be drawn from these results. First, paleogeography has a strong impact on the low-latitudes (< 30° of latitude) SST gradient because it widens the latitudinal band of relatively homogeneous warm tropical SST as a result of the opening of equatorial gateways. Second, poleward

of 40° in latitude, the paleogeography and the increase in atmospheric $p\text{CO}_2$ both contribute to the flattening of the SST gradient with a larger influence from paleogeography than from atmospheric $p\text{CO}_2$.

3.5.2 Atmosphere

In the preindustrial simulation, mean tropical atmospheric temperatures reach $\sim 23.6^\circ\text{C}$ whereas polar temperatures (calculated as the average between 80° and 90° of latitude) in the Northern and Southern Hemispheres reach around -16.8°C and -37°C respectively. The northern meridional temperature gradient is $0.69^\circ\text{C}/^\circ\text{latitude}$ while the southern latitudinal temperature gradient is $1.07^\circ\text{C}/^\circ\text{latitude}$ (Fig 9c). This significant difference is explained by the very negative mean annual temperatures over Antarctica linked to the presence of the ice sheet.

In the CT simulation, mean tropical atmospheric temperatures reach $\sim 32.3^\circ\text{C}$ whereas polar temperatures reach $\sim 3.4^\circ\text{C}$ in the Northern Hemisphere and $\sim -0.5^\circ\text{C}$ in the Southern Hemisphere, thereby yielding latitudinal temperature gradients of $0.49^\circ\text{C}/^\circ\text{latitude}$ and $0.54^\circ\text{C}/^\circ\text{latitude}$, respectively. The gradients are reduced compared to the preindustrial because the absence of year-round sea and land ice at the poles drives leads to far higher polar temperatures.

As for the SST gradients, we plot atmospheric meridional gradients by adjusting temperature values so that temperatures at the Equator are equal for each simulation (Fig 9d). This normalization reveals that the mechanisms responsible for the flattening of the gradients are different for each hemisphere. In the Southern Hemisphere high-latitudes ($> 60^\circ$ of latitude), three parameters contribute to reducing the equator-to-pole temperature gradient in the following order of importance: removal of polar ice sheets, paleogeography and increase in atmospheric $p\text{CO}_2$. In contrast, the reduction in the gradient steepness in the Northern Hemisphere high-latitudes is exclusively explained by the increase in atmospheric $p\text{CO}_2$. In the low- and mid-latitudes, this temperature gradient reduction is essentially explained by paleogeography in the Southern Hemisphere and by a similar contribution of paleogeographic changes and increase in atmospheric $p\text{CO}_2$ in the Northern Hemisphere.

4. DISCUSSION

4.1 CENOMANIAN-TURONIAN MODEL/DATA COMPARISON

The results predicted by our CT simulation can be compared to reconstructions of atmospheric and oceanic paleotemperatures inferred from proxy data (Fig 10a, b). Our SST data compilation is a modified version of Tabor et al (2016), with additional data from more recent studies (see our Supplementary data). We also compiled atmospheric temperature data obtained

from paleobotanical and paleosoil studies (see Supplementary data for the complete database and references).

The Cretaceous equatorial and tropical SST have long been believed to be similar or even lower than those of today (Sellwood et al., 1994; Crowley and Zachos, 1999; Huber et al., 2002), thus feeding the problem of “tropical overheating” systematically observed in General Circulation Model simulations (Barron et al., 1995; Bush et al., 1997; Poulsen et al., 1998). This incongruence was based on the relatively low tropical temperatures reconstructed from foraminiferal calcite (25–30°C, Fig. 9a), but subsequent work suggested that these were underestimated because of diagenetic alteration (Pearson et al., 2001; Pucéat et al., 2007). Latest data compilations including temperature reconstructions from other proxies, such as TEX86, have provided support for high tropical SST in the Cenomanian-Turonian (Tabor et al., 2016; O’Brien et al., 2017) and our tropical SST are mostly consistent with existing paleotemperature reconstructions (Fig. 10a). In the mid-latitudes (30–60°), proxy records infer a wide range of possible SST, ranging from 10°C to more than 30°C. Simulated temperatures in our CT simulation reasonably agree with these reconstructions if seasonal variability, represented by local monthly maximum and minimum temperatures (grey shaded areas, Fig 10a), is considered. This congruence would imply that a seasonal bias may exist in temperatures reconstructed from proxies, which is suggested in previous studies (Sluijs et al., 2006; Hollis et al., 2012; Huber, 2012; Steinig et al., 2020) but still debated (Tierney, 2012). There are unfortunately only a few high-latitudes SST data points available, which render the model-data comparison difficult. In the Northern Hemisphere, the presence of crocodilian fossils (Vandermark et al., 2007) in the northern Labrador Sea (~70° of latitude) imply mean annual temperature of at least 14°C and temperature of the coldest month of at least 5°C. In comparison, simulated temperatures at the same latitude in the adjacent Western Interior Sea are very similar (13.5 °C for the annual mean and 7.9 °C for the coldest month). In the Southern Hemisphere, mean annual SST calculated from foraminiferal calcite at DSDP sites 511 and 258 are between 25° and 28°C (Huber et al., 2018). Simulated annual SST reach a monthly maximum of 28°C around the location of site DSDP 258. We speculate that a seasonal bias in the foraminiferal record may represent a possible cause for this difference; alternatively, local deviations of the regional seawater $\delta^{18}\text{O}$ from the globally assumed -1‰ value may also reduce the model-data discrepancy (Zhou et al., 2008; Zhu et al., 2020).

To our knowledge, atmospheric temperature reconstructions from tropical latitudes are not available. In the mid-latitudes (30–60°), simulated atmospheric temperatures in the Southern Hemisphere reveal reasonable agreement with data whereas Northern Hemisphere mean zonal temperatures in our model are slightly warmer than that inferred from proxies (Fig 10b). At high-latitudes, the same trend is observed for atmospheric temperatures as it is for SST with data indicating higher temperatures than the model in both the Southern and Northern Hemispheres. This

inter-hemispheric symmetry in model-data discrepancy could indicate a systematic cool bias of the simulated temperatures.

4.2 RECONSTRUCTED LATITUDINAL TEMPERATURE GRADIENTS

The simulated northern hemisphere latitudinal SST gradient of ($\sim 0.45^{\circ}\text{C}/^{\circ}\text{latitude}$) is in good agreement with those reconstructed from paleoceanographic data in the Northern Hemisphere ($\sim 0.42^{\circ}\text{C}/^{\circ}\text{latitude}$) whereas it is much larger in the Southern Hemisphere ($\sim 0.39^{\circ}\text{C}/^{\circ}\text{latitude}$ vs $\sim 0.3^{\circ}\text{C}/^{\circ}\text{latitude}$) (Fig 11). This overestimate of the latitudinal gradient holds for the atmosphere as well, as gradients inferred from data are much lower (North= $0.2^{\circ}\text{C}/^{\circ}\text{latitude}$ and South= $0.18^{\circ}\text{C}/^{\circ}\text{latitude}$) than simulated gradients (North= $0.49^{\circ}\text{C}/^{\circ}\text{latitude}$ and South= $0.55^{\circ}\text{C}/^{\circ}\text{latitude}$), although the paucity of Cenomanian-Turonian continental temperatures proxy data is likely to significantly bias this comparison.

In the following, we compare our simulated gradients to those obtained in previous deep time modelling studies using recent earth system models. Because Earth system models studies focusing on the Cenomanian-Turonian are limited in numbers, we include simulations of the Early Eocene (~ 55 Ma), which is another interval of global climatic warmth (Lunt et al., 2012a, 2017) (Fig. 11). The simulated SST latitudinal gradients range from $0.32^{\circ}\text{C}/^{\circ}\text{latitude}$ to $0.55^{\circ}\text{C}/^{\circ}\text{latitude}$ (Lunt et al., 2012; Tabor et al., 2016; Zhu et al., 2019; Fig. 11) and the atmospheric latitudinal gradients from $0.33^{\circ}\text{C}/^{\circ}\text{latitude}$ to $0.78^{\circ}\text{C}/^{\circ}\text{latitude}$ (Huber and Caballero, 2011; Lunt et al., 2012; Niezgodzki et al., 2017; Upchurch et al., 2015; Zhu et al., 2019; Fig. 11). For a single model and a single set of boundary conditions (Cretaceous or Eocene), the lowest latitudinal gradient is obtained for the highest $p\text{CO}_2$ value. However, when comparing different studies with the same model (Cretaceous vs Eocene using the ECHAM5 model; REF) it is not the case: the South Hemisphere atmospheric gradient obtained for the Eocene with the ECHAM5 model is always lower than those obtained for the Cretaceous with the same model, regardless of the $p\text{CO}_2$ value (Fig. 11 and Supplementary Data). These results show the major role of boundary conditions (in particular paleogeography) in defining the latitudinal temperature gradient. IPSL-CM5A2 predicts SST and atmosphere gradients that are well within the range of other models of comparable resolution and complexity. Models almost systematically simulate larger gradients than those obtained from data (Fig. 11, see also Huber, 2012). The reasons behind this incongruence are debated (Huber, 2012) but highlight the need for more data and for challenging the behavior of complex earth system models, in particular in the high latitudes. Studies have demonstrated that models are able to simulate lower latitudinal temperature gradients under specific conditions such as anomalously high CO_2 concentrations (Huber and Caballero, 2011), modified cloud properties and radiative parameterizations (Upchurch et al., 2015; Zhu et al., 2019) or lower paleo elevations and/or more extensive wetlands (Hay et al., 2019). Finally,

Commented [MG6]: you need a reference here

from a proxy perspective, it has been suggested that a sampling bias could exist, with a better record of temperatures during the warm season at high latitudes and during the cold season in low latitudes (Huber, 2012). Such possible biases would help reduce the model-data discrepancy, in particular for atmospheric temperatures (Fig 10b), as high-latitude reconstructed temperatures are more consistent with simulated summer temperatures whereas the consistency is better with simulated winter temperatures in the mid- to low-latitudes, but further work is required to unambiguously demonstrate the existence of these biases.

4.3 PRIMARY CLIMATE CONTROLS

The earliest estimates of climate sensitivity (or the temperature change under a doubling of the atmospheric $p\text{CO}_2$) predicted a 1.5 to 4.5°C temperature increase, with the most likely scenario providing an increase of 2.5°C (Charney et al., 1979; Barron et al., 1995; Sellers et al., 1996; IPCC, 2014). Our modelling study predicts an atmospheric warming of 11.1°C for the CT. The signal is notably due to a 9°C warming in response to the fourfold increase in $p\text{CO}_2$, which converts to an increase of 4.5°C for a doubling of $p\text{CO}_2$ (assuming a linear response). This climate sensitivity agrees with the higher end of the range of previous estimates (+ add references again). However, our simulated climate sensitivity could be slightly lower as the simulations are not completely equilibrated (Fig. 1). The latest generation of Earth system models used in deep-time paleoclimate also show an increasingly higher climate sensitivity to increased CO_2 (Hutchinson et al., 2018; Golaz et al., 2019; Zhu et al., 2019), suggesting that the sensitivity could have been underestimated in earlier studies. For example, the recent study of Zhu (2019), using an up-to-date parameterization of cloud microphysics in the CESM1.2 model, proposes an Eocene Climate Sensitivity of 6.6°C for a doubling of CO_2 from 3 to 6 PAL.

We have shown that $p\text{CO}_2$ is the main controlling factor for atmospheric global warming whereas the effects of the paleogeography (warming) and reduced solar constant (cooling) nearly cancel each other out at the global scale (see also Lunt et al., 2016). These results agree with previous studies suggesting that $p\text{CO}_2$ is the main factor controlling climate (Barron et al., 1995; Crowley and Berner, 2001; Royer et al., 2007; Foster et al., 2017). However, we also demonstrate that paleogeography plays a major role in the latitudinal distribution of temperatures and impacts oceanic temperatures (with a similar magnitude than a doubling of $p\text{CO}_2$), thus confirming that it is also a critical driver of the Earth's climate (Poulsen et al., 2003; Donnadieu et al., 2006; Fluteau et al., 2007; Lunt et al., 2016). The large climatic influence of the continental configuration has not been reported for paleogeographic configurations closer to each other, e.g., the Maastrichtian and Cenomanian (Tabor et al., 2016). The main features influencing climate in our study (i.e. the configuration of

Commented [MG7]: dont forget to do this !

equatorial and polar zonal connections and the land/sea distribution) are indeed not fundamentally different in the two geological periods investigated by Tabor et al. (2016). Paleogeography is thus a first-order control on climate over long timescales.

Early work has suggested that high latitude warming can be amplified in deep time simulations by rising CO₂ via cloud and vegetation feedbacks (Otto-bliesner and Upchurch, 1997; Deconto et al., 2000) or by increasing ocean heat transport (Barron et al., 1995; Schmidt and Mysak, 1996; Brady et al., 1998), in particular when changing the paleogeography (Hotinski and Toggweiler, 2003). Our study confirms that the paleogeography is a primary control on the steepness of the oceanic meridional temperature gradient. Furthermore, paleogeography is the only process, among those investigated, that controls both the atmosphere and ocean temperature gradients in the tropics and it has a greater impact than atmospheric CO₂ on the reduction of the atmospheric temperature gradient at high latitudes in the Southern Hemisphere between the CT and the preindustrial. The increase in *p*CO₂ appears as the second most important parameter controlling the SST gradient at high latitudes and is the main control of the reduced atmospheric gradient in the Northern Hemisphere due to low cloud albedo feedback. The effect of paleovegetation on the reduced temperature gradient is marginal at high latitudes in our simulations, in contrast to the significant warming reported in early studies (Otto-bliesner and Upchurch, 1997; Upchurch, 1998; Deconto et al., 2000) but in agreement with more recent model simulations suggesting a limited influence of vegetation in the Cretaceous high-latitudes warmth (Zhou et al., 2012). However, our modeling setup prescribes boreal vegetation at latitudes higher than 50° whereas evidence exist to support the development of evergreen forests poleward of 60° of latitude (Sewall et al., 2007; Hay et al., 2019) and of temperate forests up to 60° of latitude (Otto-bliesner and Upchurch, 1997). The presence of such vegetation types could change the albedo of continental regions but also heat and water vapor transfer by altered evapo-transpiration processes, thus leading to warming amplification at high-latitudes and reduced temperature gradients (Otto-bliesner and Upchurch, 1997; Hay et al., 2019). Based on these studies and on our results, we cannot exclude that different types of high-latitude could promote a greater impact of paleovegetation in reducing the temperature gradient.

5. CONCLUSIONS

To quantify the impact of major climate forcings on the Cenomanian-Turonian climate, we perform a series of 6 simulations using the IPSL-CM5A2 earth system model in which we incrementally implement changes in boundary conditions on a preindustrial simulation to obtain ultimately a simulation of the Cenomanian-Turonian stage of the Cretaceous. This study confirms the primary control exerted by atmospheric *p*CO₂ on atmospheric and sea-surface temperatures, followed by

paleogeography. In contrast, the flattening of meridional SST gradients between the preindustrial and the CT is mainly due to paleogeographic changes and to a lesser extent to the increase in $p\text{CO}_2$. The atmospheric gradient response is more complex because the flattening is controlled by several factors including paleogeography, $p\text{CO}_2$ and polar ice sheet retreat. While predicted oceanic and atmospheric temperatures show reasonable agreement with data in the low and mid latitudes, predicted temperatures in the high latitudes are colder than paleotemperatures reconstructed from proxies, which leads to steeper equator-to-pole gradients in the model than [those](#) inferred from proxies. However, this mismatch, often observed in data-model comparison studies, has been reduced in the last decades and could be further resolved by considering possible sampling/seasonal biases in the proxies and by continuously improving model physics and parameterizations.

DATA AVAILABILITY

Code availability:

LMDZ, XIOS, NEMO and ORCHIDEE are released under the terms of the CeCILL license. OASIS-MCT is released under the terms of the Lesser GNU General Public License (LGPL). Figure 1: Time series for mean annual oceanic temperatures. (a) Sea-surface temperature and (b) deep-ocean (2500 m) temperature. The piControl and 1X-NOICE simulations are perfectly equilibrated. The 4X simulations still have a small linear drift, around 0.1°C/century or less : 0.07, 0.08, 0.05 and 0.01°C/century during the last 500 years for SST of 4X-NOICE, 4X-NOICE-PFT-SOIL, 4X-NOICE-PFT-SOIL-SOLAR and 4X-CRETACEOUS respectively; 0.11, 0.08, 0.07 and 0.06°C/century during the last 500 years, for deep-ocean of 4X-NOICE, 4X-NOICE-PFT-SOIL, 4X-NOICE-PFT-SOIL-SOLAR and 4X-CRETACEOUS respectively.

Figure 2: Modern and Cenomanian-Turonian geographic configurations used for the piControl and 4X-CRETACEOUS simulations respectively, and meridional oceanic area anomaly between Cretaceous paleogeography and Modern geography.

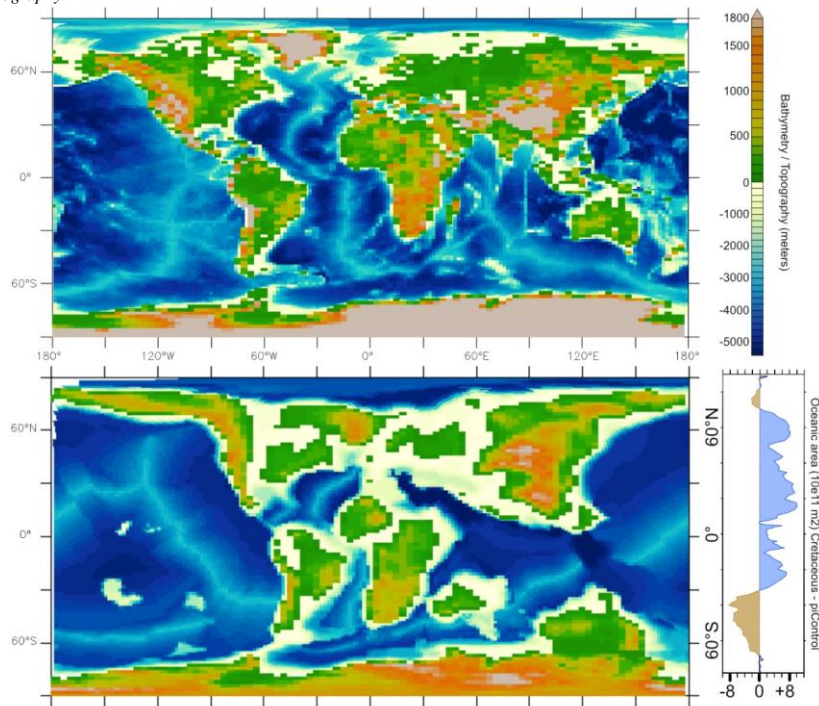

Figure 3: Evolution of Albedo (surface and planetary) and emissivity, in percentages and of T2M (°C) from piControl to 4X-CRETACEOUS simulations. The major change is always recorded with the change of pCO₂ between 1X-NOICE and 4X-NOICE simulations.

Figure 4: T2M (°C) for (a) piControl initial simulation and (g) Cretaceous final simulation, and anomalies (°C) for intermediate simulations: (b) 1X-NOICE-piControl, (c) 4X-NOICE-1X-NOICE, (d) 4X-NOICE-PFT-SOIL – 4X-NOICE, (e) 4X-NOICE-PFT-SOIL-SOLAR – 4X-NOICE-PFT-SOIL, (f) 4X-CRETACEOUS - 4X-NOICE-PFT-SOIL. White color (not represented in the colourbar) correspond to areas where the anomaly is not statistically significant according to the student test.

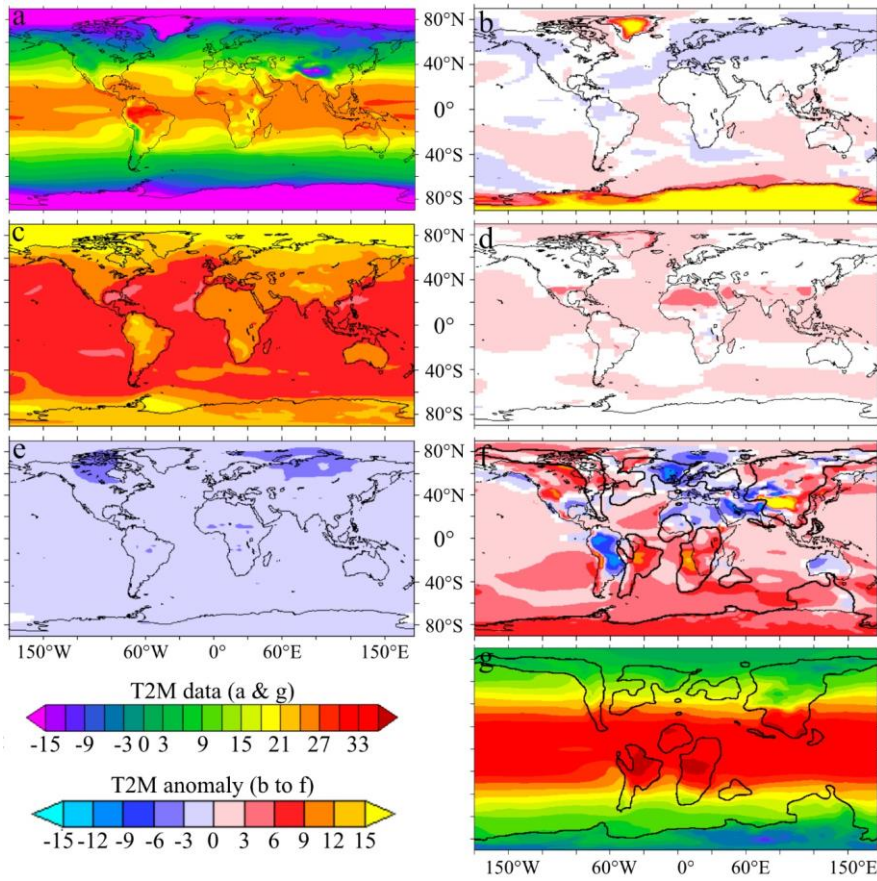

Figure 5: Mean annual cloudiness for 1X-NOICE and 4X-NOICE simulations. (a) Anomaly of total cloudiness (4X-NOICE – 1X-NOICE). (b) Low-altitude cloudiness (Below 680 hPa of atmospheric pressure - solid curves) and high-altitude cloudiness Above 440 hPa of atmospheric pressure - dashed curves) for 1X-NOICE (black) and 4X-NOICE (red) simulations.

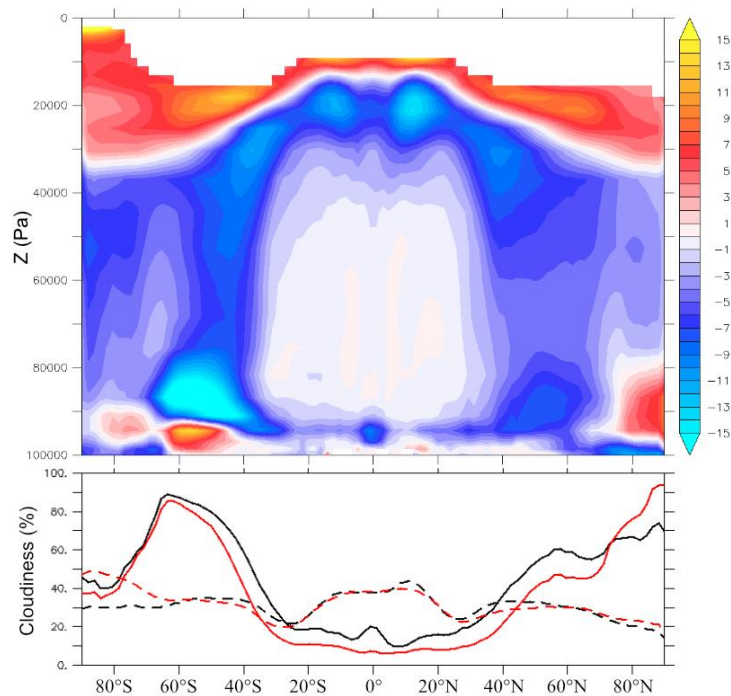

Figure 6: T2M (°C) mean annual meridional gradients for 4X-NI-PFT-SOIL-SOLAR (black) and 4X-CRETACEOUS (red) simulations. Solid curve corresponds to annual average, dashed curves correspond to winter and summer values. The 4X-CRETACEOUS simulation is generally warmer than the 4X-NI-PFT-SOIL-SOLAR-SOLAR simulation, with the exception of the boreal summer.

Figure 7: Surface currents for 4X-NOICE-PFT-SOIL-SOLAR (left) and 4X-CRETACEOUS (right) simulations. (a), (b) Intensity of surface circulation (Sv – Annual Mean for 0-80 meters of water depth). Strong equatorial winds lead to the

formation of an equatorial circumglobal current. (c), (d) Intensity of surface circulation (S_v – Annual Mean for 0-80 meters of water depth). The closure of the Drake passage (DP-300 meters of water depth) leads to the suppression of the ACC.

Figure 8 - (a), (b) Global mean annual meridional stream-function (S_v) for the first 300 meters of water depth. Red and blue colors indicate clockwise and anti-clockwise circulation respectively. (a): 4X-NI-PFT-SOIL-SOLAR and (b) 4X-CRETACEOUS. (c) Oceanic heat transport for 4X-NI-PFT-SOIL-SOLAR and 4X-CRETACEOUS simulations. Positive and negative values indicate northward and southward transport direction, respectively.

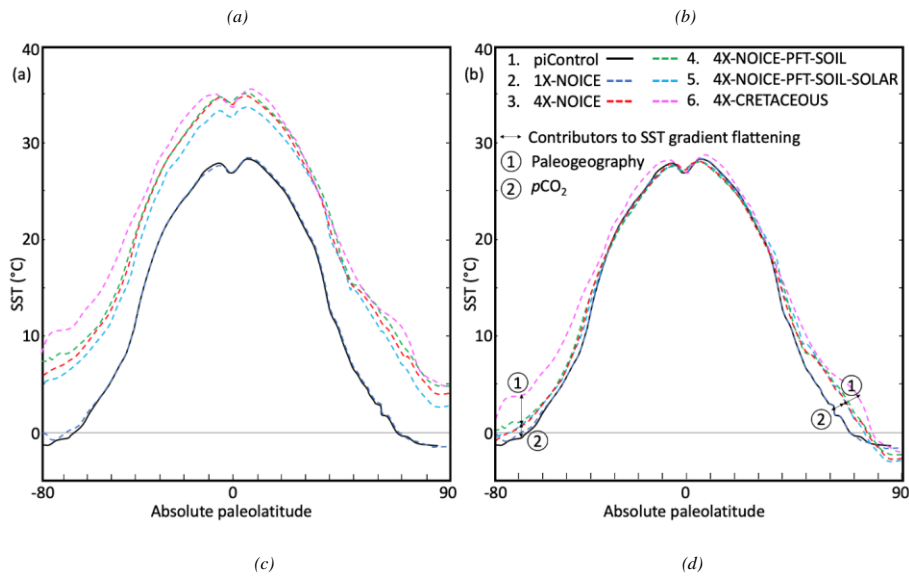

Figure 9: (a) Mean annual meridional Sea-Surface Temperature gradients for all simulations. (b) Same SST curves than (a) but superimposed such as equator temperatures are equal, allowing to compare the steepness of the curves. (c) Meridional atmospheric surface temperature gradients for all simulations. (d) Same curves than (c) but superimposed such as equator temperatures are equal.

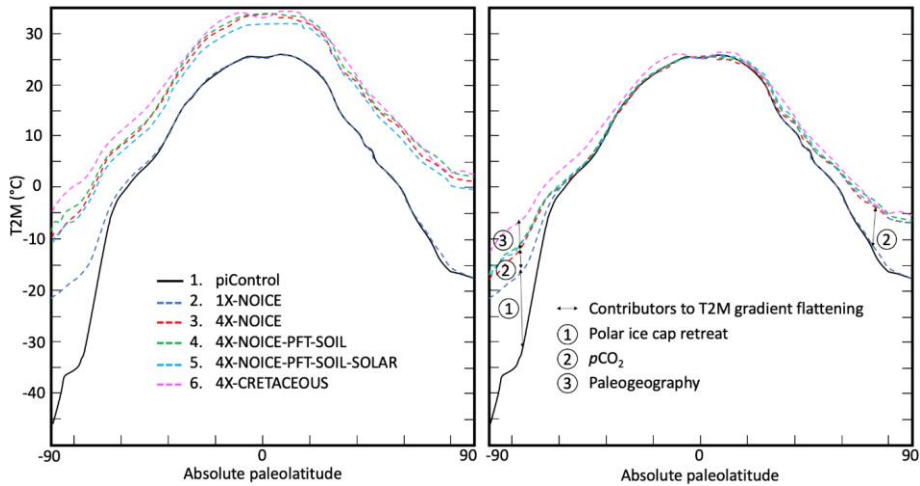

Figure 10: Meridional surface temperature gradients for the 4X-CRETACEOUS simulation. (a) Oceanic temperatures: the solid line corresponds to the mean annual temperature obtained from the modeling. Dashed lines correspond to winter and summer seasonal averages. The grey shaded areas correspond to local monthly temperatures. Data points are obtained with several proxies for the Cenomano-Turonian period. The green data point is obtained from TEX 86 for the Maastrichtian (70 Ma) and extrapolated for 90 Ma. The Huber et al. (2018) point is obtained from $\delta^{18}O$ on foraminifera and the Vandenmark et al., 2007 point is interpreted from the presence of crocodilian fossils. MAT=Mean Annual Temperature, CM=Coldest Month. (b) Atmospheric temperatures: same legend as (a) for modeled temperatures. Data points are obtained from several proxies including CLAMP analysis on paleofloras, leaf analyses, paleosol-derived climofunction or bioclimatic analysis. Symbols represent mean annual temperatures and solid lines associated ranges/errors. Dashed lines represent monthly mean temperatures. Orange data points are for Cenomano-Turonian ages (100-90 Ma), blue data points for Albian and green data points for Coniacian-Santonian (88-85 Ma).

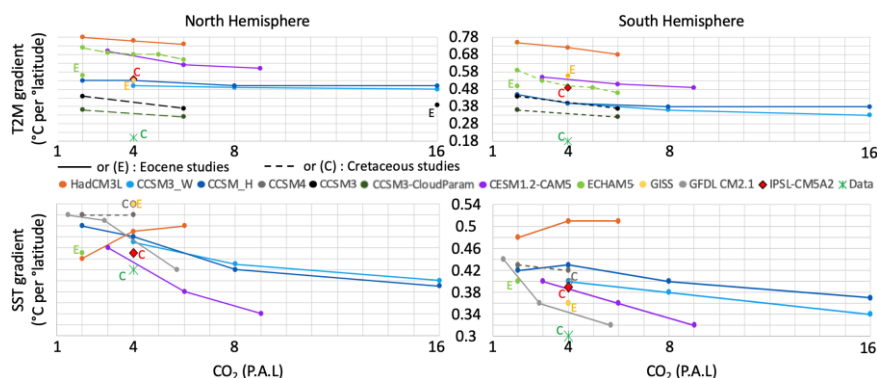

Figure 11: Plot of atmospheric and sea surface mean annual temperature gradients vs pCO_2 for different modelling studies and data compilation. Data gradients are plotted for a default pCO_2 value of 4 P.A.L. Gradients are expressed in $^{\circ}C$ per $^{\circ}latitude$ and are calculated from 30 to 80 degrees of latitude. Gradients linked by a line correspond to studies realized with the same model & paleogeography. Solid lines or gradients marked with a (E) correspond to an Eocene paleogeography. Dashed lines or gradients marked with a C correspond to a Cretaceous paleogeography.
